†Electronic Supplementary Information (ESI) available

Abstract

Heteroscorpionate-based [(L10O)MoO₂Cl] and [(L3S)MoO₂Cl] complexes containing an interchangeable third heteroatom donor have been utilized for the systematic investigation of oxygen atom transfer (OAT) reactivity. The detection of phosphoryl intermediates and products in the reaction pathway were probed by UV-Vis, mass spectrometry, and ³¹P NMR spectroscopy. The OAT reactivity of the metal complexes toward PPh₃ were monitored by UV-Vis spectroscopy under pseudo-first order conditions. The sterically encumbered (L10O) ligand gives rise to isolable *trans* and *cis* isomers of [(L10O)MoO₂Cl] allowing investigation into the role of geometry on OAT reactivity. The OAT reactivity of the *cis* isomer of (L10O)MoO₂Cl demonstrated a dramatic solvent dependence, in which the reaction proceeded at a measureable rate only in pyridine. However, the *trans* counterpart reacted in all solvents and at much faster rates. The catalytic oxidation of PPh₃ to OPPh₃ by *trans*-[(L10O)MoO₂Cl] and *cis*-[(L3S)MoO₂Cl] complexes using DMSO as an oxygen donor was monitored by ³¹P NMR in DMF at 30°C with rates, $k_{\text{cat}} = 4.26 \times 10^{-5} \text{ s}^{-1}$ and $5.28 \times 10^{-5} \text{ s}^{-1}$, respectively.

Introduction

Oxygen atom transfer (OAT) is an important class of chemical transformation in biology and chemistry.¹⁻³ Mononuclear molybdenum enzymes are ubiquitously involved in this two electron process by shuttling a terminal oxo from the metal center to an acceptor and vice versa with the molybdenum center interchanging between the +6 and +4 oxidation states.⁴ These enzymes have been classified into three major families: Sulfite Oxidase (SO), Xanthine Oxidase (XO), and DMSO Reductase (DMSOR), in which all the active sites contain conserved pterin-dithiolene ligation to the molybdenum.⁵ The proper regulation and function of these enzymes affect the environment, biological metabolism, and homeostasis. For instance, mutation on the structural gene of SO causes complications from dysfunctional lipid metabolism to fatal neurological abnormalities.⁵

The utility of facially tridentate scorpionate and heteroscorpionate model systems has provided important spectroscopic and OAT mechanistic insights into the function and mechanism of mononuclear molybdoenzymes despite their incorporating pyrazolate donors rather than the sulfur rich environment native to the enzymes.⁶⁻¹⁸ Mechanistically a variety of computational studies have proposed that the oxygen atom transfer performed by these molybdoenzymes follows an inner sphere electron transfer mechanism proceeding through the associative formation of a bridging intermediate that subsequently decomposes to products via a dissociative pathway.¹⁹ Utilizing the Tp* system, Basu and co-workers provided direct evidence of this predicted intermediate with the crystal structure of the phosphoryl adduct complex [Tp*MoOCl(OPMe₃)].²⁰⁻²⁴ We have observed similar species via ESI-MS and UV-Vis spectroscopy utilizing the sulfur rich [TmMeMoO₂Cl] complex.²⁵

Prompted by Basu's work and our own results, we have expanded on this research by investigating our family of heteroscorpionate complexes of the type [LMoO₂Cl], where L = (L10O) and (L3S) shown in scheme 1. Over the last several years, we have demonstrated that these dioxo-Mo(VI) complexes significantly influenced OAT reactivity based on contribution of the third heteroatom, i.e. alkoxide, phenol, carboxylate, or thiolate.¹³ In addition, the introduction of steric bulk into the phenolate ligand has allowed for the isolation of both *cis* and *trans* geometric isomers and we have studied the isomerization rates from kinetically labile isomer to the thermodynamically favored product for both Mo(V) and Mo(VI). The effect of geometry on OAT reactivity of the dioxo-Mo(VI) complexes has also been superficially studied.^{12,14,16,18} Finally, we demonstrated a metal ion dependence between Mo(VI) and W(VI) on both isomerization kinetics and OAT reactivity.^{15,26} Herein, utilizing complexes of [(L10O)MoO₂Cl] and [(L3S)MoO₂Cl], we explore the effect of solvent on OAT reactivity along with the detection of [(L10O)MoOCl(OPPh₃)] and [(L3S)MoOCl(OPPh₃)] intermediates by mass spectrometry and ³¹P NMR spectroscopy. Moreover, utilizing ³¹P NMR spectroscopy, we have monitored the ability of these complexes to mediate catalytic OAT between DMSO and triphenylphosphine.

Results

***trans*-[(L10O)MoO₂Cl].** Isolation of the pure *trans* isomer of [(L10O)MoO₂Cl] remains difficult due to its rapid conversion to the thermodynamically more stable *cis* isomer under a variety of conditions. The mechanism of isomerization at the metal center is proposed to occur via a trigonal twist mechanism as the bromide-chloride exchange was not observed by mass

spectrometry.¹⁶ Optimal synthetic efforts have yielded a product with an 11:1 *trans/cis* ratio based on proton NMR.¹⁵

Examination of the OAT reactivity of *trans*-[(L10O)MoO₂Cl] in acetonitrile, DMF, benzene, and pyridine under pseudo-first order conditions with 50-fold excess of phosphine was monitored by UV-vis spectroscopy. On mixing of acetonitrile solution of *trans*-[(L10O)MoO₂Cl] and phosphine, the optical spectra depicted in figure 1 (top) showed a rapid increase of the band at 400 nm and simultaneous appearance of the weak, broad, d-d transition band in the 600-800 nm region (data not shown) as the direct result of the two electron reduction of Mo(VI) to Mo(IV). This reaction proceeded rapidly leading to a bright green solution. After several minutes in acetonitrile and as shown in figure 1 (bottom), the band at 400 nm decreased exponentially with concomitant growth of a new peak at 360 nm with an isosbestic point at 370 nm. The d-d band at 600-800 nm also decreased slightly in intensity. These UV-vis spectral features are identical to those reported during the OAT chemistry of the related, [TmMeMoO₂Cl]. The rapid growth of the 400 nm peak corresponds to the formation of the intermediate [(L10O)MoOCl(OPPh₃)]. The assignment of 400 nm peak observed in the UV-vis as being due to the phosphine adduct was confirmed by ESI-MS recorded in positive mode in acetonitrile which revealed a cluster centered at 812.8 m/z, (figure 2) consistent with the simulated isotope pattern expected for the bridging intermediate (figure S1). Furthermore, monitoring the OAT reaction in benzene by ³¹P NMR revealed three peaks, assignable to PPh₃ (-4 ppm), OPPh₃ (26 ppm), and the [(L10O)MoOCl(OPPh₃)] at 51 ppm. The subsequent exponential decay of the 400 nm band represents the dissociation of the OPPh₃ product from the primary coordination sphere. This is consistent with the solvent assisted dissociative interchange (I_d) mechanism proposed for a related system.²⁵

The effect of pyridine on the reaction run in DMF or acetonitrile was probed through UV-vis spectroscopy by allowing steady-state formation of the phosphine adduct to age for ~ 10 minutes followed by addition of an aliquot of pyridine. Introduction of pyridine resulted in the more rapid decay of the 400 nm shoulder with concomitant growth of bands at 500 nm and in the 600-800 nm region. The final spectrum is identical to the previously isolated and characterized *trans*-[(L10O)MoOCl(py)]. Probing the same sample via ESI mass spectrometry also detected [(L10O)MoOCl(py)] at 613 m/z (figure 3) confirmed by the simulated isotope pattern (data not shown). When the OAT was performed in pure pyridine, rapid formation of the [(L10O)MoOCl(OPPh₃)] intermediate was again witnessed at 400 nm along with the rise of the broad Mo(IV) d-d transition band at 600-800 nm (figure 4). The stability of phosphine bound intermediate in pyridine is much less than that in DMF, acetonitrile, and benzene however as indicated by the near simultaneous appearance of a shoulder at 500 nm corresponding to formation of both the *trans*-[(L10O)MoOCl(py)] complex and the intermediate. Figure 5 shows the deconvoluted individual UV-vis spectra in the OAT reaction profile. Nevertheless the solvation of the phosphine oxide bound intermediate by pyridine is still quite slow relative to that seen with [TmMeMoOCl(OPPh₃)] and [Tp*MoOCl(OPPh₃)] likely due to the steric protection of the intermediate afforded by the biphenyl rings of the (L10O) ligand.

***cis*-[**(L10O)MoO₂Cl**]**. The pure *cis* isomer of [**(L10O)MoO₂Cl**] was synthesized according to published protocol by heating a crude isomeric mixture in DMF to assure the complete conversion of all the *trans* to the *cis* isomer. Under identical OAT conditions in acetonitrile and DMF, the *cis* isomer appears completely unreactive based on the unchanged UV-vis spectrum over many days. Moreover, analysis of the OAT reaction mixture by ESI-MS revealed no detectable phosphine adduct and only the starting dioxo complex was observed. However, when the OAT reaction of *cis*-[**(L10O)MoO₂Cl**] was performed in pyridine as a solvent, OAT occurred and could be followed by the appearance of the Mo(IV) d-d transition band at 600-800 nm and the intense absorption at 500 nm reminiscent of the optical spectrum of *trans*-[**(L10O)MoOCl(py)**] (figure S2). Thus in contrast to *trans*-[**(L10O)MoO₂Cl**] which underwent OAT reaction in all solvents (*vide supra*), the reaction with the *cis* isomer proceeded only in pyridine. In addition, and consistent with our previously reported OAT results, even in pyridine the *cis* isomer reacted at least 20 times slower than the *trans* isomer (figure S3).¹² The redox potential contribution to the substantial variation in the two observed rates of OAT reactivity appears to be inadequate because the difference in the Mo(VI/V) redox potential between the isomers is quite small (<100 mv),¹⁵ which cannot account for the substantial variation in the two observed rates. More interestingly, the lack of OAT reactivity by the *cis* isomer in acetonitrile and DMF compared to pyridine suggests the crucial effect of solvent. The ¹H NMR of *cis*-[**(L10O)MoO₂Cl**] in d₅-pyridine revealed only the *cis* isomer, eliminating the possibility that rapid isomerization of the *cis* to the *trans* isomer in pyridine could account for its reactivity in pyridine but not in ACN or DMF.²⁹

In order to better understand the effect of geometry at the dioxo center with OAT rate we conducted computational studies (for details see Table S1). The two reaction steps i.e. binding to phosphine and displacement of the phosphine oxide by solvent, were computationally modeled for the [**(L10O)MoO₂Cl**] complexes in order to determine the origin of the observed stereospecificity. Transition states for three pathways were identified for step 1 of the reaction (scheme 2): binding of the phosphine to either oxo group of the *cis* reactant (*cis* path); binding to the *trans* reactant at the oxo group O2, which is *trans* to the ligand oxygen atom O1 (*trans t* path); and binding to the *trans* at the *cis* oxo group O3, which is roughly 90 degrees from O1 and O2 (*trans c* path). The pseudo-first order rate constants in Table 1 were obtained by combining zero-point and thermal energy corrections to obtain predicted free energies of activation G_a . The computational results given in Table 1 correctly predict that the *trans c* reaction pathway is the most likely, and that step 1 tends to be slower than step 2. However, the agreement is only qualitative, with rate constants much too low predicted for k_2' and for the *cis* k_1' . Rate constants are difficult to predict quantitatively for complex systems, where a 1 kcal/mol error in G_a corresponds to more than a factor of 5 in reaction rate. For step 1, the computed entropic contribution to G_a alone is nearly 13 kcal/mol. Solvent effects have also been neglected in the present calculations.

Natural bond order (NBO) analyses were carried out on the step 1 reactants and transition states in an attempt to explain the greater relative stability of the *trans c* transition state. Selected results are summarized in Table 2. Before the reaction, the electron-deficient metal pulls electron density from the ligands in the complex. In the *cis* reactant, each of the three oxygens is

aligned along a different axis in the octahedral complex, and this allows maximum donation into the empty *d* orbitals of the metal, accounting for the relatively strong Mo-O1 bond ($R=1.971$ Å for *cis*, 2.018 Å for *trans*) and the slight relative stability of the *cis* to the *trans* overall, with ΔG (*cis-trans*) = 2.3 kcal/mol. When the phosphine attaches to either of the two oxo's, electron density donated by the phosphorus increases the electron density at the metal, which weakens the Mo-O1 bond. In all three transition states, the Mo-O1 bond distance has increased to 2.045 Å, but this is a greater weakening of the bond in the *cis* structure than in the *trans*, and therefore the *cis* has the highest barrier to reaction.

Of the two oxo's in the *trans* path, O3 is the better electron acceptor (charge = $-0.39e$ for O3, $-0.45e$ for O2) because it is able to donate more electron density than O2, which shares an axis with O1. This favors O3 for attachment of the phosphine, and is consistent with the smaller change in Mo-O3 bond distance upon formation of the transition state in the *trans c* path than the *trans t* ($\Delta R=0.106$ Å for *trans c* and $\Delta R=0.131$ Å for *trans t*). During reaction, the HOMO of the PMe₃ preferentially acts as a sigma donor to the lowest unoccupied orbital of one of the oxygens. As shown in Figure 6, the LUMOs in each of the three step 1 transition states span a metal *d* orbital and an Mo-O π^* orbital ending at the attachment site of the phosphine.

***cis*-[(L3S)MoO₂Cl].** The UV-Vis spectrum for the OAT reaction of [(L3S)MoO₂Cl] with phosphine in DMF and acetonitrile shows an absorbance increase at 500 nm and between 600-900 nm producing a red solution after ~ 10 minutes (figure S4). The non-exponential kinetics and the lack of isosbestic points suggest a competing elementary reaction. The red solution was found to persist for weeks. We postulated that the red solution did not contain the phosphine adduct or [(L3S)MoOCl(solvent)] species, but rather it was the μ -oxo dimer, as the addition of pyridine had no effect. Based on published results and our other observations reported here either the phosphine oxide intermediate or the solvent adduct would be expected to react with pyridine to yield the mononuclear species, i.e. [(L3S)MoOCl(py)]. Immediate analysis of the OAT reaction mixture in acetonitrile by mass spectrometry did led to the detection of the [(L3S)MoOCl(OPPh₃)] intermediate isotopic cluster at 704 amu (figure S5) however also detected was the presence of [(L3S)MoOCl]₂O at 867 amu (figure S6). Analysis after one day showed that the phosphine intermediate had decomposed, but the μ -oxo dimer cluster at 867 m/z remained. A reasonable explanation for these observations is that the less bulky methyl groups on the thiolate ligand do not prevent μ -oxo dimerization of the [(L3S)MoOCl(solvent)] species formed after OAT.

In contrast, mixing of the metal complex and phosphine in pyridine generated [(L3S)MoOCl(OPPh₃)] followed by the growth of the 500 nm band and d-d transition band from Mo(IV) at 800 nm with a tight isosbestic point at 405 nm indicating only two absorbing species in solution (figure S7). Figure 7 shows the individual deconvoluted UV-vis spectra in the OAT reaction profile. The rate of formation of [(L3S)MoOCl(OPPh₃)] extracted at 500 nm is $k_{1\text{obs}} = 6.96 \times 10^{-4} \text{ s}^{-1}$ (Table 3). Upon reaching steady state, the phosphoryl adduct decomposed by releasing OPPh₃ as monitored by the decreased absorption intensity at 500 nm to complete the oxygen atom transfer. The decomposition rate of intermediate to products is $k_{2\text{obs}} = 5.92 \times 10^{-5} \text{ s}^{-1}$.

Catalytic Oxygen Atom Transfer. The catalytic OAT of *trans*-[(L10O)MoO₂Cl] and *cis*-[(L3S)MoO₂Cl] were monitored in 50:50 v/v DMF and d₆-DMSO with 10-fold excess of PPh₃ by ³¹P NMR. The *cis* isomer of [(L10O)MoO₂Cl] was not examined due to its extremely slow OAT rate in any solvent other than pure pyridine and pyridine has been shown to inhibit the catalytic cycle.²⁵ The reaction (Me₂S=O + PPh₃ → Me₂S + OPPh₃) was followed by the growth of phosphine oxide (27 ppm) over time. The rate of catalytic OAT by *trans*-[(L10O)MoO₂Cl] is $k_{\text{cat}} = 4.26 \times 10^{-5} \text{ s}^{-1}$. Upon completion of the reaction, precipitation of a white solid ensued which was isolated by vacuum filtration and washed with copious amounts of hexane to remove excess solvents and OPPh₃. IR characterization of the white solid confirmed its identity as [(L10O)MoO₂Cl], thus provided direct evidence that the mononuclear complex is the active catalyst. *cis*-[(L3S)MoO₂Cl] also demonstrated catalytic conversion of phosphine (-5 ppm) to phosphine oxide (27 ppm) as shown by ³¹P NMR with $k_{\text{cat}} = 5.28 \times 10^{-5} \text{ s}^{-1}$. A stoichiometric OAT reaction of *cis*-[(L3S)MoO₂Cl] with PPh₃ monitored by ³¹P NMR in DMF showed 100% conversion to OPPh₃ followed by rapid coloration to dark purple red indicating μ -oxo dimer formation. The experiment indicates that the mononuclear complex transferred an oxygen atom to the phosphine acceptor, but dimerization occurred soon after as the ligand lacks steric bulk to protect the Mo center from dimerization.

Experimental

Preparation of Compounds. All syntheses were performed under a dinitrogen or argon atmosphere using standard Schlenk or drybox techniques. Acetonitrile, ether, dichloromethane and THF were freshly purified using an Innovative Technology solvent purification system. All other solvents were dried with appropriate drying agents and distilled prior to use. Silica gel (SilicAR Silica Gel 150, 60-200 Mesh 60 – 200 mesh) used in adsorption chromatography was obtained from Mallinckrodt while the filtering agent Celite was obtained from Aldrich. The heteroscorpionate ligands (L10OH, L3SH) utilized in this study was synthesized according to previous reports. The synthesis and detailed characterization of [(L10O)MoO₂Cl] stereoisomers and [(L3S)MoO₂Cl], are reported elsewhere.^{13,15}

Physical Methods. Electrospray mass spectra (ESI-MS) were recorded on a Finnigan LCQ ion-trap mass spectrometer equipped with an ESI source (Finnigan MAT, San Jose, CA) in positive ion mode. A PC with Navigator software version 1.2 (Finnigan Corp., 1995-1997), was used for data acquisition and plotting. Isotope distribution patterns were simulated using the program Molecular Weight Calculator 6.42. GC-MS detection of dimethylsulfide was performed on the Varian Chrompack Saturn 2000R GC-MS containing auto sampler operated under the Varian MS Workstation System Control software version 6.6. UV-visible spectra were recorded using a Cary 50 UV-visibility spectrophotometer under PC control using the Cary WinUV software. Infrared spectra were collected KBr disks on a ThermoNicolet Nexus 670 FT-IR spectrometer under PC control and are reported in wavenumbers.

Oxygen Atom Transfer Kinetics. A 2.5 mM solution of LMoO₂Cl in acetonitrile, DMF, benzene, and pyridine was reacted with an excess of 50-fold PPh₃ at 30(1)°C using a jacketed quartz cell attached to a circulating bath controlling the temperature. Fresh samples were prepared for each kinetic run and solutions were preequilibrated at 30°C in a water bath prior to

any measurements. Tight isosbestic points were observed throughout the reaction indicating the presence of only two absorbing species. All reactions were monitored using a Cary 50 UV-Vis spectrometer under PC control. Rate constants for OAT were extracted at 700 nm or 500 nm and where appropriate global fitting of the data were performed with OLIS Spectral Works version 3.0.8 kinetic software.

Catalytic OAT Studies. In a typical experiment, 6.5 mg (1.26×10^{-5} mol) of the metal complex and a 10-fold excess of PPh_3 (6.29×10^{-3} mol) were dissolved in a 50:50 v/v mixture of DMF and d_6 -DMSO with a total volume of 1.0 mL in a NMR tube. The ^{31}P NMR kinetic experiment was performed on a 400 MHz Varian FT-NMR spectrometer with the automated temperature controller set at 30°C. Prior to kinetic measurements the NMR sample was equilibrated at 30°C and spectra were recorded every 15 minutes under PC control. The detection of dimethyl sulfide (DMS) by GC-MS confirmed the reduction of DMSO via oxo abstraction from Mo(IV) intermediate. In control experiments without metal complex under identical conditions, OAT conversion of PPh_3 to OPPh_3 was not observed.

Computational Methods. Full geometry optimizations, vibrational calculations, and natural bond order (NBO) analyses were carried out with Gaussian 03,³⁰ using the B3LYP density functional method,^{31,32} with Dunning's cc-pVDZ basis set³³ for the main group atoms and the CEP-121G effective core potential and basis set of Stevens et al.³⁴ for the metal center. In the computations, PMe_3 was used in place of PPh_3 for simplicity.

Acknowledgements

This work was supported in part by grants CHE-0313865 (CJC) and CHE-0202535 (ALC) from the NSF. The NSF-MRI program grants CHE-0320848 and CHE-0216563 are acknowledged for support of the X-ray diffraction and computational facilities, respectively, at San Diego State University. We thank Dr. LeRoy Lafferty for assistance with the ^{31}P NMR kinetic studies.

trans t TS LUMO

Figure 7. OAT reaction of PPh_3 with *cis*- $[(\text{L3S})\text{MoO}_2\text{Cl}]$ in pyridine. Right: the biphasic OAT kinetics extracted at 500 nm (right) where the points are the data and the solid line a fit to an $\text{A} \rightarrow \text{B} \rightarrow \text{C}$ kinetic scheme. Left: Spectral deconvolution of the OAT reaction profile where the Solid line represents the spectra of the starting *cis*- $[(\text{L3S})\text{MoO}_2\text{Cl}]$, the dashed line the phosphine adduct, and the dotted line $[(\text{L3S})]\text{MoOCl}(\text{py})$.

Table 1. B3LYP energies and free energies of activation and pseudo-first order rate constants.

step 1	E_a (kcal/mol)	G_a (kcal/mol)	k_1' (s⁻¹)
<i>trans c</i>	7.3	20.2	$2 \cdot 10^{-4}$
<i>trans t</i>	11.9	24.3	$2 \cdot 10^{-7}$
<i>cis</i>	15.0	26.9	$3 \cdot 10^{-9}$
step 2	E_a (kcal/mol)	G_a (kcal/mol)	k_2' (s⁻¹)
<i>trans c</i>	14.7	29.6	$3 \cdot 10^{-9}$

Table 2. Selected NBO charges and bond lengths.

	Reactants		TS1 complexes		
	<i>Trans</i>	<i>Cis</i>	<i>Trans c</i>	<i>Trans t</i>	<i>Cis</i>
O1 charge (e)	-0.68	-0.66	-0.71	-0.72	-0.71
O2,O3' charge (e)	-0.45	-0.41	-0.48	-0.67	-0.45
O3 charge (e)	-0.39	-0.41	-0.59	-0.44	-0.63
R(Mo-O1) (Å)	2.019	1.971	2.045	2.045	2.046
R(Mo-O2,O3') (Å)	1.733	1.721	1.728	1.864	1.710
R(Mo-O3) (Å)	1.719	1.722	1.825	1.708	1.846

Table 3. Kinetic Parameters for OAT.

Metal complex	Solvent	k_1 (s ⁻¹)	k_2 (s ⁻¹)
<i>trans</i> -(L10O)MoO ₂ Cl	ACN	4.18 x 10 ⁻²	3.80 x 10 ⁻⁴
	DMF	6.08 x 10 ⁻³	
	DMF/pyridine		1.99 x 10 ⁻⁴
<i>cis</i> -(L10O)MoO ₂ Cl	pyridine		1.82 x 10 ⁻⁴
<i>cis</i> -(L3S)MoO ₂ Cl	pyridine	6.96 x 10 ⁻⁴	9.11 x 10 ⁻⁶
	ACN and DMF ^a		5.92 x 10 ⁻⁵

^aThe k_1 and k_2 could not be quantitatively measured due to competing μ -oxo dimer reaction.

trans t path

trans c path

cis path
(O₃ and O₃' equivalent until attachment)

*Graphical abstract - synopsis

The effects of stereochemistry (*cis* and *trans*) on OAT between heteroscorpionate dioxo Mo (VI) complexes and triphenylphosphine are examined.
