Abstract

The volatility of secondary organic aerosol (SOA) formed through cloud processing (aqueous hydroxyl radical ($\cdot\text{OH}$) oxidation and droplet evaporation) of methylglyoxal (MGly) was studied. Effective vapor pressure and effective enthalpy of vaporization ($\Delta H_{\text{vap},\text{eff}}$) were determined using 1) droplets containing MGly and its oxidation products, 2) a Vibrating Orifice Aerosol Generator (VOAG) system, and 3) Temperature Programmed Desorption Aerosol-Chemical Ionization Mass Spectrometry (TPD Aerosol-CIMS). Simulated in-cloud MGly oxidation (for 10-30 min) produces an organic mixture of higher and lower volatility components with an overall effective vapor pressure of $(4\pm 7) \times 10^{-7}$ atm at pH 3. The effective vapor pressure decreases by a factor of 2 with addition of ammonium hydroxide (pH 7). The fraction of organic material remaining in the particle-phase after drying was smaller than for similar experiments with glycolaldehyde and glyoxal SOA. The $\Delta H_{\text{vap},\text{eff}}$ of pyruvic acid and oxalic acid + methylglyoxal in the mixture (from TPD Aerosol-CIMS) were smaller than the theoretical enthalpies of the pure compounds and smaller than that

estimated for the entire precursor/product mix after droplet evaporation. After 10-30 min of aqueous oxidation (one cloud cycle) the majority of the MGly + $\cdot\text{OH}$ precursor/product mix (even neutralized) will volatilize during droplet evaporation; neutralization and at least 80 min of oxidation at 10^{-12} M $\cdot\text{OH}$ (or > 12 hr at 10^{-14} M) is needed before low volatility ammonium oxalate exceeds pyruvate.

1. Introduction

There is substantial evidence for secondary organic aerosol (SOA) formation through gas-phase oxidation followed by aqueous chemistry in clouds and wet aerosol (Blando and Turpin, 2000; Ervens et al., 2011; Herrmann et al., 2015). Organic compounds are predominantly emitted in the gas-phase (Fraser et al., 1996) where they are fragmented, oxidized and form small water-soluble organic compounds, which are ubiquitous and abundant in the atmosphere (Millet, 2005; Carlton and Turpin, 2013). The chemistry of several water-soluble organics (e.g., aldehydes, organic acids, ketones, phenols, epoxides) has been studied because of their potential to form SOA in the aqueous-phase (SOA_{aq}) by means of radical chemistry (e.g., hydroxyl radical reactions) and non-radical reactions (e.g., acid or ammonium catalyzed reactions) (e.g., Ervens et al., 2011; De Haan et al., 2011; McNeill, 2015). SOA_{aq} has also been observed to form through evaporation of droplets containing single organic compounds (e.g., glyoxal, methylglyoxal) that form oligomers through self-reactions (Loeffler et al., 2006; De Haan et al., 2009). The current study focuses on droplet evaporation of products formed by the OH-initiated oxidation of methylglyoxal (MGly) with hydroxyl radicals ($\cdot\text{OH}$) in clouds (MGly SOA_{Cld}).

MGly ($\text{C}_3\text{H}_4\text{O}_2$) is a secondary gas-phase oxidation product of anthropogenic and biogenic hydrocarbons including isoprene (Atkinson and Arey, 2003; Seinfeld and Pandis, 2012; Fu et al., 2008). MGly is emitted by biomass burning (Hays et al., 2002), vehicles (Ban-Weiss et al., 2008) and from the sea surface (Lawson et al., 2015). Its gas-phase lifetime is 2 hr and 9 hr with respect to photolysis and $\cdot\text{OH}$, respectively (Atkinson 2000). MGly is water soluble (effective Henry's law constant, $H_{\text{eff}} = 3.71 \times 10^3 \text{ M atm}^{-1}$ at 25°C) (Betterton and Hoffmann, 1988) and has been measured

58 in clouds ($< 0.3\text{--}128\ \mu\text{M}$) (Munger et al., 1995). In the aqueous-phase, MGly reacts rapidly with $\cdot\text{OH}$
59 (~ 26 min aqueous lifetime with respect to $\cdot\text{OH}$) and forms several products found in the particle-
60 phase in the atmosphere (e.g., pyruvate, oxalate, and glyoxylate; Limbeck et al., 2001). At cloud
61 relevant concentrations, the reaction of MGly with $\cdot\text{OH}$ produces small carboxylic acids, mainly
62 pyruvic, acetic, and oxalic acids, and to a minor extent glyoxylic and glycolic acids (Tan et al.,
63 2010). In the highly concentrated solutions found in wet aerosols, non-radical (e.g., NH_4^+) reactions
64 become more important and radical reactions can form larger organic acids and oligomers (Lim et
65 al., 2013; McNeill, 2015). Additionally, MGly can form SOA_{aq} by self-oligomerization through aldol
66 condensation reactions in evaporating aqueous droplets (Loeffler et al., 2006; De Haan et al., 2009).

67 While SOA_{aq} formation is being added to chemical transport models (McNeill, 2015), a
68 better understanding of chemical transformations that occur during droplet evaporation (Loeffler et
69 al., 2006; De Haan et al., 2009; Ortiz-Montalvo et al., 2012, 2014) and the thermodynamic properties
70 of the SOA_{aq} mixture are needed to aid these efforts (Tsigaridis and Kanakidou, 2003). Michaud et
71 al. (2009) found that SOA_{aq} formed through aqueous OH oxidation of methacrolein and droplet
72 evaporation became less volatile with increasing oxidation (reaction time). Ortiz-Montalvo et al.
73 (2012) provided values of effective vapor pressure ($\sim 10^{-7}$ atm) and enthalpy of vaporization (~ 70
74 kJ/mol) for the precursor/product mixture formed through aqueous $\cdot\text{OH}$ oxidation (10–30 min) and
75 droplet evaporation of glycolaldehyde. They hypothesized that the vapor pressure of glycolaldehyde
76 SOA_{aq} would be orders of magnitude lower if the organic acid products (e.g. oxalate) were
77 neutralized to organic salts. Evidence to support this was provided by evaporating droplets of oxalic
78 acid and ammonium oxalate. More recently, Ortiz-Montalvo et al. (2014) verified that the volatility
79 of a glyoxal + $\cdot\text{OH}$ precursor/product mixture (after 10 min reaction) was significantly reduced when
80 the mixture was neutralized from pH 3 to pH 7 through the addition of ammonium hydroxide.

81 The present study provides, to our knowledge, the first reported estimates of the effective
82 vapor pressure ($p'_{L,\text{eff.}}$) and enthalpy of vaporization ($\Delta H_{\text{vap,eff}}$) of MGly cloud SOA_{aq} (SOA_{Cld})
83 formed through $\cdot\text{OH}$ oxidation and droplet evaporation in the presence (pH 7) and absence (pH 3) of
84 NH_4OH . This work seeks to better understand the gas-particle partitioning of SOA_{Cld} .

85 2. Methods

86 2.1 Overview

87 The purpose of this work is to characterize the volatility of SOA_{Cl_d} formed from in-cloud
88 oxidation of MGly by OH radicals ([•]OH) followed by droplet evaporation. Vibrating Orifice Aerosol
89 Generator (VOAG) and Temperature Programmed Desorption Aerosol Chemical Ionization Mass
90 Spectrometry (TPD Aerosol-CIMS) systems were used to determine $p'_{L,eff}$ and $\Delta H_{vap,eff}$ of the MGly
91 + [•]OH precursor/product mix in evaporating droplets for two different atmospheric scenarios. The
92 aqueous chemistry of MGly and [•]OH has previously been validated by comparing predicted and
93 measured precursor/product concentration dynamics in laboratory batch reactor experiments (Tan et
94 al., 2010; Lim et al., 2013). We used this chemistry to determine the precursor/product compositional
95 mix resulting from the [•]OH oxidation (10^{-12} M) of 5 μ M MGly in cloud droplets (10-30 min) using 1)
96 a batch reactor and 2) a continuously stirred tank reactor (CSTR) approximation. Mimic solutions
97 prepared with these compositions were used in droplet evaporation experiments. The VOAG system
98 provided information about the volatility behavior of the mixture, whereas the TPD Aerosol-CIMS
99 characterized the behavior of individual species within the mixture.

100 2.2 Chemical Modeling

101 Previously published chemical models were used (Tan et al., 2010; Lim et al., 2013). In batch
102 reactor modeling (Tan et al., 2010), the initial MGly concentration was 5 μ M, within the
103 concentration range found in cloud water (Munger et al., 1995). This corresponds to a gas-phase
104 MGly concentration of ~ 1 ppb, given a Henry's law constant of $H = 3.71 \times 10^3$ M atm⁻¹ (Betterson
105 and Hoffmann, 1988). MGly decreased as the reaction proceeded. The concentration of [•]OH was
106 held constant at 10^{-12} M, an upper bound for cloud water (Ervens et al., 2014). For CSTR modeling
107 (Lim et al., 2013), the aqueous MGly concentration was maintained always at 5 μ M and the [•]OH
108 concentration at 10^{-12} M. Note, modeled composition at 10^{-13} and 10^{-14} M OH are provided in Fig.
109 S1.

110 MGly is formed in the atmosphere from many precursor gases; thus it is not immediately
111 apparent whether the batch reactor or CSTR approximation is more appropriate for modeling the

chemical composition. If gas-phase production of MGly is slow relative to its aqueous oxidation, a batch reactor may be a better approximation. If, on the other hand, gas-phase MGly production (and aqueous uptake) is rapid relative to aqueous oxidation, MGly will continue to be replenished in the aqueous-phase as oxidation takes place, and the aqueous oxidation system will be better represented as a CSTR. However, you will find below that effective vapor pressures determined for both Batch and CSTR assumptions were similar. This chemistry is likely to be oxidant (rather than MGly) limited (Ervens et al., 2014).

2.3 Mimic Samples

Mimic solutions were prepared to match the chemical composition 10-30 minutes into batch and CSTR reactions. Concentrations of species were scaled up 13-130 times for CSTR, and 25-250 times for batch) creating 6 concentrations from approximately 500-4000 $\mu\text{M-C}$ all above the detection limits of the droplet evaporation system, while maintaining the same distribution of species. Thus, droplet evaporation experiments were conducted with solutions that were initially more concentrated than typical cloud droplets and as a result, experiments do not include any chemistry that occurs at the initial (most dilute) stage of droplet evaporation. Mimics were prepared using 18 M Ω milli-Q water, methylglyoxal (37.8%; Sigma-Aldrich) and pyruvic (99.1%; Sigma-Aldrich), oxalic (0.1008 N; Fluka Analytical), and acetic (99.99%; Sigma-Aldrich) acids. To study the effects of increasing pH, we added ammonium hydroxide (29.6% as ammonia (NH_3); J.T. Baker) to selected CSTR mimics.

2.4 VOAG Droplet Evaporation Experiments

Monodisperse droplets (droplet diameter, $D_d = 17.9 \pm 0.4 \mu\text{m}$, $n=3$, $r^2=0.99$) of mimic samples were generated and evaporated using a VOAG (TSI Model 3450; Berglund and Liu, 1973) followed by a dilution drying chamber (residence time 6 s, $12 \pm 3\%$ RH, $24.1 \pm 0.4^\circ\text{C}$). The diameter of the resulting particles (e.g., SOA) was measured with an optical particle counter (OPC) downstream of an ionizer, as described previously (Ortiz-Montalvo et al., 2012) and in Supplemental Information.

137 The volatility of SOA_{Cld} was assessed as described previously (Ortiz-Montalvo et al., 2012).
 138 Briefly, six dilutions (0 - 4000 $\mu\text{M C}$) of each mimic solution and organic standard (acetic, oxalic,
 139 succinic, glutaric, and tartaric acids) were passed through the VOAG. Resulting droplets were dried
 140 to ~10% RH; their dry diameter was measured in the OPC and the mass of residual particles (*PM*
 141 *mass*) was calculated using assumptions given in Table S1). In addition, each mimic solution was
 142 analyzed for total organic carbon (TOC) and converted to organic matter (*OM mass*). The *PM mass*
 143 of the organic standards was regressed on *OM mass*, and the slopes of each were evaluated against
 144 their corresponding liquid vapor pressures (p°_{L}) (SIMPOL group contribution method; Pankow and
 145 Asher, 2008) and enthalpies of vaporization (ΔH_{vap}) (Joback and Reid, 1987; group contribution
 146 method using normal boiling points to estimate ΔH_{vap} of pure compounds). Sigmoidal fits were
 147 obtained since the *PM mass* divided by droplet *OM mass* ($PM\ mass / OM\ mass_{(\text{droplet})}$) reflects the
 148 particle fraction (i.e., fraction of the total droplet organic matter that remained in the particle-phase).
 149 Because some organic compounds, like tartaric acid, retain water even at 5% RH (Peng et al., 2001),
 150 a correction was made to the original sigmoidal curve to account for the effect of residual water on
 151 particle density, as described previously (Ortiz-Montalvo et al., 2012). The $p'_{\text{L},\text{eff}}$ and $\Delta H_{\text{vap},\text{eff}}$ of the
 152 mimics (mix of MGly precursors and products) were estimated from the corrected sigmoidal curves.
 153 The estimated $p'_{\text{L},\text{eff}}$ for malonic acid ($1 \pm 1 \times 10^{-7}$ atm), analyzed as an independent check (6 dilutions
 154 between 0-3000 $\mu\text{M C}$ from 0.999 %, Sigma-Aldrich), is of the same order of magnitude as the
 155 calculated theoretical value ($2 \pm 2 \times 10^{-7}$ atm) (Pankow and Asher, 2008). The estimated $\Delta H_{\text{vap},\text{eff}}$
 156 (72 ± 2 kJ/mol) differed from the theoretical value by 4% (69.12 ± 1.79 kJ/mol) (Joback and Reid,
 157 1987). A ~17% uncertainty is introduced because of differences in refractive index of malonic acid
 158 (1.479) and polystyrene latex particles (1.59; used for OPC manufacturer-supplied calibration).
 159 Droplet evaporation experiments were also run with 1 mM standards: oxalic acid, oxalic acid
 160 + ammonium hydroxide, ammonium oxalate (99.0%; Fluka Analytical), pyruvic acid, pyruvic acid +
 161 ammonium hydroxide, and sodium pyruvate (100 mM; Thermo Scientific) (Fig. 1). Ammonium
 162 hydroxide, when used, was added to adjust the solution to pH 7. The ratio of the residual PM volume

163 to $OM\ mass_{(droplet)}$ ($PM\ vol. / OM\ mass_{(droplet)}$) for oxalic acid + ammonium hydroxide was identical
164 to that of ammonium oxalate, verifying that the addition of ammonium hydroxide effectively
165 neutralized organic acids (Fig. 1). Note that $PM\ vol. / OM\ mass_{(droplet)}$ is proportional to the fraction
166 remaining in the particle-phase and increases with decreasing vapor pressure. In addition,
167 neutralization of oxalic acid (ammonium oxalate production) had a larger effect on $PM\ vol. / OM$
168 $mass_{(droplet)}$ than pyruvic acid neutralization (Fig. 1), presumably because ammonium oxalate has a
169 lower vapor pressure (Paciga et al., 2014).

170 2.5 TPD Aerosol-CIMS Analysis

171 Bulk mimic solutions were also analyzed by TPD Aerosol-CIMS, as described previously
172 (Ortiz-Montalvo et al., 2014; Drozd et al., 2014; Hakkinen et al., 2014; McNeill et al., 2007).
173 Briefly, bulk mimic solutions were aerosolized, dried and combined with a dry N₂ dilution flow (3.5-
174 9.5 L/min) to ~12% RH. The aerosol had a lognormal number size distribution with a geometric
175 mean particle diameter of 29±3 nm and geometric standard deviation of 1.3 (measured by scanning
176 mobility particle sizer after drying). Organics were then volatilized at 25-116°C for gas-phase
177 detection by CIMS (McNeill et al., 2007; Ortiz-Montalvo et al., 2014). The residence time from
178 atomization to CIMS detection was ~6 seconds. CIMS measurements were made in negative mode
179 using I⁻ reagent ions.

180 MGly and oxalic, pyruvic and acetic acids are detectable in the negative mode. Oxalic acid
181 and MGly both appear at m/z 217 as $I\cdot C_2H_2O_4$ and $I\cdot C_3H_4O_2\cdot H_2O$, respectively. Pyruvic acid
182 appears at m/z 215 as $I\cdot C_3H_4O_3$. Acetic acid is detected at m/z 187 as $I\cdot C_2H_4O_2$; however, no
183 analysis of acetic acid was performed because initial evaluations showed a constant signal over the
184 range of temperature tested, suggesting it was present entirely in the gas-phase at 25°C. The
185 Clausius-Clapeyron relation was used to calculate the $\Delta H_{vap,eff}$ (kJ/mol) for individual species
186 present in the mixture (Ortiz-Montalvo et al., 2014).

187 Each mimic solution was analyzed at least twice. A solution of 1 mM oxalic acid standard
188 (from 0.05 M; Fluka Analytical) was also analyzed (only once); its measured $\Delta H_{vap,eff}$ (69±33

189 kJ/mol) was within 22-29% of the theoretical value (91-101 kJ/mol; Yaws, 2003) for the temperature
190 range used (25-37°C).

191 **3. Results**

192 *3.1 Modeled Droplet Composition*

193 Precursor and product concentration dynamics as well as composition of mimics at 10 and 30
194 minutes are shown (Fig. 2) because these are typical cloud droplet life times (Desboeufs et al., 2003;
195 Ervens and Volkamer, 2010). Among the four mimics, the 30 min Batch and 10 min CSTR mimic
196 samples were the most different. Therefore, we selected these for droplet evaporation experiments, in
197 order to bound the range of $p'_{L,eff}$ and $\Delta H_{vap,eff}$ of the precursor/product mixtures formed after one
198 cloud processing cycle of MGly in the presence of $\cdot\text{OH}$. (Note, an air mass encountering cloudy
199 conditions typically undergoes multiple (~10) cloud cycles of 10-30 min duration over the course of
200 a day (Ervens and Volkamer, 2010).) The continuous accumulation of pyruvic acid (pink line)
201 observed in the CSTR model is due to the continuous dissolution of gas-phase MGly in the CSTR
202 model. Formaldehyde mainly forms from the reaction of $\cdot\text{OH}$ and acetic acid (a major product of
203 MGly + $\cdot\text{OH}$) (Tan et al., 2012; Lim et al., 2013).

204 *3.2 VOAG – Vapor Pressure and Enthalpy of Vaporization*

205 The $p'_{L,eff}$ and $\Delta H_{vap,eff}$ of CSTR and Batch mimics were comparable: $3\text{-}6 \times 10^{-7}$ atm and 67-
206 69 kJ/mol, respectively (Table 1, Figs. 3 and S1). The 30 min Batch mimic, which had a higher
207 percentage of organic acids and less MGly, had a slightly lower but not significantly different $p'_{L,eff}$
208 than the 10 min CSTR mimic ($p = 0.01$, t-test, two-tailed). Similarly, the reduction in $p'_{L,eff}$
209 accomplished by neutralization (pH 7) of the CSTR mimic was small (factor of two) and the
210 difference was not significant ($p = 0.01$, t-test, two-tailed).

211 Fig. 3 shows the residual particle mass (*PM mass*) and mass of organic matter in the droplet
212 (*OM mass_(droplet)*) from droplet evaporation experiments conducted with organic acid standards and
213 mimics. The *PM mass* of organic acid standards (oxalic, succinic, glutaric, and tartaric acids) is well
214 correlated with *OM mass_(droplet)* ($r^2 = 0.84\text{-}0.99$) with the exception of acetic acid, which is volatile.

215 The slopes ($PM\ mass / OM\ mass_{(droplet)}$) reflect the fraction of total droplet organic matter remaining
 216 in the particle-phase (e.g., particle fraction) and are reported in Table 1 with coefficients of
 217 determination (r^2) of $PM\ mass$ on $OM\ mass_{(droplet)}$ for Batch 30 min (solid blue circles) and CSTR 10
 218 min (at pH 3 and pH 7; solid black triangles and red squares, respectively). SOA yields are reported
 219 in Section S3. The sample with the highest particle fraction was the neutralized (pH 7) 10 min CSTR
 220 mimic. In contrast, the sample with the lowest particle fraction was the 10 min pH 3 CSTR mimic.

221 The sigmoidal curve in the inset of Fig. 3 is a fit to the $PM\ mass / OM\ mass_{(droplet)}$ versus $\log$
 222 p'_L for the organic acid standards, uncorrected (dashed) and corrected (solid) for the upper bound
 223 influence of retained water on density. Also shown in the inset are the corresponding $PM\ mass / OM$
 224 $mass_{(droplet)}$ values for the Batch (inset middle blue dashed arrow) and CSTR samples (inset upper red
 225 arrow for pH 7; lower green dashed arrow for pH 3), pointing to their corresponding estimated $p'_{L,eff}$.
 226 The $p'_{L,eff}$ values, taken from the sigmoidal regression, are reported in Table 1. Overall, the
 227 volatilities of the three mimics were within a factor of two, with the largest difference found between
 228 the 10 min CSTR mimic at pH 7 (3×10^{-7} atm) and pH 3 (6×10^{-7} atm). There was a factor of two
 229 decrease in volatility with increasing pH. A decrease in volatility with addition of ammonium is
 230 consistent with lower reported vapor pressures of organic acid salts compared to their corresponding
 231 acids (Fig. 1). The decrease is modest presumably because of the modest effect of ammonia addition
 232 on pyruvic acid (compared to the much larger effect of ammonia addition on oxalic acid).

233 Values of $\Delta H_{vap,eff}$ for Batch and CSTR mimics (Table 1) were estimated using a similar
 234 approach (Fig. S2). $\Delta H_{vap,eff}$ estimates (~ 68 kJ/mol) for the mix of MGly + 'OH precursors and
 235 products (mimics) fall within the range of the ΔH_{vap} values of the pure individual components that
 236 comprised the CSTR and Batch samples (23-73 kJ/mol, at normal boiling point; Yaws 2003). No
 237 significant difference was observed between $\Delta H_{vap,eff}$ estimates for the different mimics. A difference
 238 of ~ 40 -50% is observed between theoretical (molar-weighted enthalpies) and effective ΔH_{vap} (Table
 239 1). Possible reasons are discussed below.

240 This work suggests that the MGly + $\cdot$ OH precursor/product mix created after processing
241 through one cloud cycle (10-30 min) has a $p'_{L,eff}$ and $\Delta H_{vap,eff}$ of $(4\pm 7) \times 10^{-7}$ atm and 68 ± 3 kJ/mol,
242 respectively. Note that longer in-cloud reaction times (i.e., multiple cloud cycles) will push the
243 product mix toward oxalate, which if present as a salt would lower the volatility of the mixture
244 substantially (see ammonium oxalate slopes, Fig.1). Ammonium oxalate has a vapor pressure of
245 $\sim 10^{-11}$ atm (U.S. EPA 2010).

246 3.3 TPD Aerosol-CIMS – Enthalpy of Vaporization of Methylglyoxal Mimics

247 $\Delta H_{vap,eff}$ of selected individual organic aerosol species formed from the CSTR and Batch
248 mixtures and estimated by TPD Aerosol-CIMS are given in Table 2. While oligomers might have
249 formed during the atomization and drying processes, their evolution was not observed at the
250 temperatures used. $\Delta H_{vap,eff}$ values for pyruvic acid (m/z 215) and oxalic acid + methylglyoxal (m/z
251 217) were both lower than the theoretical ΔH_{vap} values of the pure compounds. For example, the
252 $\Delta H_{vap,eff}$ of pyruvic acid in the mixture was ~ 5 -19 kJ/mol compared to the theoretical ΔH_{vap} of pure
253 pyruvic acid (48-52 kJ/mol) in the temperature range of 25-116°C (Yaws 2003). The reduction in
254 $\Delta H_{vap,eff}$ for a compound in a mixture compare to the ΔH_{vap} of the pure compound is consistent with
255 previous findings by Ortiz-Montalvo et al. (2014), McNeill et al. (2007) and Donahue et al. (2005).
256 Changes in $\Delta H_{vap,eff}$ with pH are within the measurement uncertainty (Table 2). TPD Aerosol-CIMS
257 supporting data can be found in Section S2 of Supplemental Information; these results are discussed
258 in further detail below.

259 4. Discussion and Conclusions

260 In this study, effective enthalpies of vaporization were measured for mimics of the MGly +
261 $\cdot$ OH precursor/product mixtures present after one cycle (10-30 min) of simulated cloud processing
262 (68 ± 3 kJ/mol; VOAG) and for selected individual compounds in aerosols generated from the mixture
263 (5-19 kJ/mol pyruvic acid, 31-34 kJ/mol MGly + oxalic acid; TPD Aerosol-CIMS). The VOAG
264 system also measured $p'_{L,eff}$ of the MGly + $\cdot$ OH precursor/product mixture, $(4\pm 7) \times 10^{-7}$ atm, which

decreased by only a factor of two with neutralization from pH 3 to 7 (i.e., through addition of ammonium hydroxide).

The $\Delta H_{vap,eff}$ of the MGly + $\cdot$ OH precursor/product mixture (VOAG system) was similar (Table S2) to that measured for the precursor/product mix from glycolaldehyde + $\cdot$ OH (~70 kJ/mol) and glyoxal + $\cdot$ OH (~70 kJ/mol) using the same approach (Ortiz-Montalvo et al., 2012; 2014). VOAG results fell within the range of ΔH_{vap} values for the pure individual components in the mixtures. The observed difference (~40-50%) between theoretical (molar-weighted) and VOAG-estimated enthalpies reported here (Table 1) could be due to (1) compounds formed during droplet evaporation (e.g., methylglyoxal oligomers, imidazoles) that were not included in the theoretical calculation, and/or (2) retention of residual water in the measurements of the VOAG, which would result in larger measured diameters (thus PM volume and mass) and consequently larger $PM\ mass / OM\ mass_{(droplet)}$ ratios and higher VOAG enthalpy estimates. Based on this assessment the values we report in Table 1 are likely to be upper-bound estimates. In contrast to the VOAG results for $\Delta H_{vap,eff}$ of precursor/product mixtures, the (TPD Aerosol-CIMS) $\Delta H_{vap,eff}$ of individual compounds within the mimic aerosols were smaller than the $\Delta H_{vap,eff}$ values of the pure compounds, in agreement with other TPD Aerosol-CIMS measurements of the ΔH_{vap} of individual species within internally mixed aerosol particles.

The $\Delta H_{vap,eff}$ values obtained by the VOAG method for the MGly + $\cdot$ OH mimic mixtures are much larger than those obtained for pyruvic acid and oxalic acid + MGly from the TPD Aerosol-CIMS method. This is not surprising since the TPD Aerosol-CIMS tracks the evolution of individual organic components from the aerosols, whereas in the VOAG experiments $PM\ mass / OM\ mass_{(droplet)}$ values reflect the fraction of the *total* mimic organic matter that remains in the particle-phase. This quantity is compared to $PM\ mass / OM\ mass_{(droplet)}$ values for single standards of known $\Delta H_{vap,eff}$. So the results reflect the $\Delta H_{vap,eff}$ of the entire mimic mixture and any products formed during the evaporation process (e.g., oligomers). For example, MGly is among the components of this mixture. A portion of MGly will evaporate and a portion is likely to oligomerize during droplet evaporation. In either case it will influence the $\Delta H_{vap,eff}$ of the mixture as measured in the VOAG. On the other

hand, in the TPD Aerosol-CIMS, the $\Delta H_{vap,eff}$ values of MGly oligomers were not measured because they do not volatilize at the temperatures used in our experiments ($\leq 116^\circ\text{C}$).

The $p'_{L,eff}$ of the CSTR and Batch methylglyoxal + $\cdot\text{OH}$ precursor/product mimic mixtures are very similar to the $p'_{L,eff}$ ($1-2 \times 10^{-7}$ atm) measured for the mixture produced from the OH-initiated oxidation of (1 mM) glycolaldehyde with ($\sim 10^{-12}$ M) $\cdot\text{OH}$ in a batch reactor using the same VOAG system (Ortiz-Montalvo et al., 2012). In the glycolaldehyde study, we argued that the $p'_{L,eff}$ would be orders of magnitude lower if the organic acids were neutralized (pH 7) since organic salts have much lower vapor pressures than the organic acids. We still believe that this is true for glycolaldehyde because oxalate is a major oxidation product, at least at 40 min, and the volatility of ammonium oxalate is 4 orders of magnitude lower than that of oxalic acid (Fig. 1). Additionally, the fact that oxalic acid is found in the atmosphere predominantly in the particle-phase (Limbeck et al., 2001), despite its high vapor pressure, suggests that it is present in the atmosphere in a lower volatility form (e.g., a salt or complex). Furthermore, in our glyoxal study we found that neutralization did in fact reduce the volatility of aqueous glyoxal + $\cdot\text{OH}$ mixture (Ortiz-Montalvo et al., 2014). However, in the current MGly study, the addition of ammonia (from pH 3 to 7) to the CSTR 10 min sample (i.e. to form ammonium pyruvate) lowered the $p'_{L,eff}$ by only a factor of 2 and not orders of magnitude as we expected. The degree of vapor pressure reduction is likely to depend on the properties of the organic salts being formed as seen in Fig. 1. In Fig. 1, values of PM volume/OM mass (from the VOAG System) and sub-cooled liquid vapor pressures are provided for pyruvic and oxalic acids and their ammonium and/or sodium salts. Clearly, ammonium salt formation reduces the vapor pressure of pyruvate, but not to the degree observed for oxalate. Nevertheless, atmospheric measurements have found that most pyruvate is in the particle-phase (e.g., 61%) (Limbeck et al., 2001). These results and our previous findings indicate that organic salt formation can play an important role in the properties and fate of SOA formed through cloud processing, but that it will depend on the gas-particle partitioning of the formed salts. There is a need to better understand the predominant forms that these organic acids take in the atmosphere because of their effect on gas-particle partitioning of SOA.

319 While this work produced a mix of lower and higher volatility products with an intermediate
320 volatility (3×10^{-7} atm in the presence of ammonia), there are several ways in which the volatility of
321 MGly SOA_{Cld} mix might decrease further. 1) Because of its high oxygen-to-carbon ratio (O:C ~ 0.8-
322 1.1), we expect this material to re-dissolve and undergo additional cloud processing cycles. Based on
323 our model results we expect oxalate to exceed pyruvate after 10-20 cloud cycles (one or two days)
324 given 10^{-12} M OH (Fig. S3). Note that ammonium oxalate has a vapor pressure of $\sim 10^{-11}$ atm (Paciga
325 et al, 2014; Fig. 1). Thus we expect 1-2 days of cloud processing to lead to a substantial reduction in
326 the volatility of the MGly + $\cdot$ OH precursor/product mix. However if the aqueous OH concentration
327 is 10^{-13} or 10^{-14} M, 20 to more than 70 cycles (a day to in excess of a week) of cloud processing
328 would be required before oxalate dominates. Concentrations of OH radicals in clouds are not well
329 constrained due to an incomplete understanding of aqueous-phase OH production and loss,
330 especially involving organics. 2) Aqueous chemistry can also continue in the wet aerosol that is
331 present in the cloud outflow. The much higher concentrations in wet aerosols alter the chemistry and
332 promote oligomer formation through radical and non-radical reactions (DeHaan et al., 2011; Lim et
333 al., 2013). 3) The predominant chemical form of the organic acid products of MGly + $\cdot$ OH (pyruvate,
334 oxalate, acetate) in the atmosphere is not known. Binding with other cations (e.g. to form other salts)
335 or with transition metals (Weller et al., 2014) could potentially reduce the volatility of this mix. This
336 could occur via acid displacement reactions (e.g., Laskin et al., 2012) or reactions with polyvalent
337 metal ions (e.g., Furukawa and Takahashi, 2011).

338 In conclusion, effective vapor pressure ($p'_{L,eff.}$) and enthalpy of vaporization ($\Delta H_{vap,eff.}$) values
339 were estimated for the aqueous oxidation products of methylglyoxal with $\cdot$ OH (as modeled at cloud
340 relevant conditions using two atmospheric scenarios) followed by droplet evaporation (MGly
341 SOA_{Cld}). The volatility assessment indicated that neutralization of MGly + $\cdot$ OH organic acid
342 products with ammonia resulted in only a modest (not statistically significant) decrease in the $p'_{L,eff.}$
343 ($3\text{-}6 \times 10^{-7}$ atm) and increase in the $\Delta H_{vap,eff.}$ (67-69 kJ/mol). The volatility of MGly SOA_{Cld} was also
344 comparable between the Batch (MGly depletion) and CSTR (MGly at steady-state) models. Our
345 study shows that for one cloud cycle the MGly + $\cdot$ OH precursor/product mix (even neutralized) has

an intermediate vapor pressure, meaning that a majority of this organic mixture will not remain in a dry particle after droplet evaporation. There are several ways that the fraction found in the particle-phase might be greater (lower volatility): (1) pyruvate (main product) could be present in a different chemical form, (2) chemical processing could take place for multiple cloud cycles (one to several days) to reach a maximum yield of oxalate, (3) chemical processing could continue in the wet aerosol formed after droplet evaporation forming low-volatility oligomers, (4) water bound to the hygroscopic particle could enhance retention of the soluble, intermediate volatility products. The gas-particle partitioning of atmospheric pyruvate remains uncertain and affects our understanding of methylglyoxal as a SOA_{Cld} precursor.
